## **Theory**

## **Classification and Regression Trees**

In this section, I have presented some new methods that are being widely used in the era of "Big Data" and "Data Science". Engineers and computer scientists called this area machine learning or "deep learning" for use in problems associated with very large data sets. I have provided several files on the class BOX under a folder, entitled CART\_stuff. These provide additional discussion/examples for various aspects of trees and random forest, including topics for bagging/boosting methods. As there are many details associated with these methods, I will demonstrate some of the methods with a commonly used data entitled the Boston Housing Data.

I have included two examples for CART; a classification tree (for use with a binary endpoint) and a regression tree (for use with a continuous endpoint).

#### **SAS - HPSPLIT Procedure**

The HPSPLIT procedure is a high-performance procedure that builds tree-based statistical models for classification and regression. The procedure produces classification trees, which model a categorical response, and regression trees, which model a continuous response. Both types of trees are referred to as decision trees because the model is expressed as a series of if-then statements.

The predictor variables for tree models can be categorical or continuous. The model is based on a partition of the predictor space into non-overlapping segments, which correspond to the terminal nodes or leaves of the tree. The partitioning is done recursively, starting with the root node, which contains all the data, and ending with the terminal nodes. At each step of the recursion, the parent node is split into child nodes through selection of a predictor variable and a split value that minimize the variability in the response across the child nodes.

Tree models are built from training data for which the response values are known, and these models are subsequently used to score (classify or predict) response values for new data. For classification trees, the most frequent response level of the training observations in a leaf is used to classify observations in that leaf. For regression trees, the average response of the training observations in a leaf is used to predict the response for observations in that leaf. The splitting rules that define the leaves provide the information that is needed to score new data.

The process of building a decision tree begins with growing a large, full tree. Various measures, such as the Gini index, entropy, and residual sum of squares, are used to assess candidate splits for each node. The full tree can overfit the training data, resulting in a model that does not adequately generalize to new data.

To prevent overfitting, the full tree is pruned back to a smaller subtree that balances the goals of fitting training data and predicting new data. Two commonly applied approaches for finding the best subtree are cost-complexity pruning (Breiman et al. 1984) and C4.5 pruning (Quinlan 1993). For more information, see the section Building a Decision Tree.

SAS/STAT software provides many different methods of regression and classification. Compared with other methods, an advantage of tree models is that they are easy to interpret and visualize, especially when the tree is small. Tree-based methods scale well to large data, and they offer various methods of handling missing values, including surrogate splits.

However, tree models have limitations. Regression tree models fit response surfaces that are constant over rectangular regions of the predictor space, and so they often lack the flexibility needed to capture smooth relationships between the predictor variables and the response. Another limitation of tree models is that small changes in the data can lead to very different splits, and this undermines the interpretability of the model (Hastie, Tibshirani, and Friedman 2009; Kuhn and Johnson 2013).

#### **Measures of Model Fit**

Various measures of model fit have been proposed in the data mining literature. The HPSPLIT procedure measures model fit based on a number of metrics for classification trees and regression trees.

If you specify a variable in the WEIGHT statement, then the weight of an observation is the value of the weight variable for that observation. If no WEIGHT statement is specified, then the weight of each observation is equal to one. In this case, the sum of weights of observations is equal to the number of observations.

#### **Fit for Classification Trees**

The HPSPLIT procedure measures model fit based on the following metrics for classification tree: entropy, Gini index, misclassification rate (Misc), residual sum of squares (RSS), average square error (ASE, also known as the Brier score), sensitivity, specificity, area under the curve (AUC), and confusion matrix.

#### **Entropy for Classification Trees**

Entropy for classifications tree is defined as

Entropy = 
$$-\sum_{\lambda} \frac{N_{w\lambda}}{N_{w0}} \sum_{\tau} \frac{N_{w\tau}^{\lambda}}{N_{w\lambda}} \log_2 \left(\frac{N_{w\tau}^{\lambda}}{N_{w\lambda}}\right)$$

where

- $\lambda$  is a leaf
- $N_{\omega\lambda}$  is the sum of weights of observations on leaf  $\lambda$
- $N_{\omega 0}$  is the total sum of weights of observations in the entire data set
- $\tau$  is a level of the response variable
- $N_{\omega\tau}^{\lambda}$  is the sum of weights of observations on leaf that have response level

#### **Gini Index for Classification Trees**

The Gini index for classification trees is defined as

$$\mathrm{Gini} = \sum_{\lambda} \frac{N_{w\lambda}}{N_{w0}} \sum_{\tau} \frac{N_{w\tau}^{\lambda}}{N_{w\lambda}} \left(1 - \frac{N_{w\tau}^{\lambda}}{N_{w\lambda}}\right)$$

#### **Misclassification Rate for Classification Trees**

Misclassification (Misc) comes from the number of incorrectly predicted observations. It is defined as

$$\mathrm{Misc} = \frac{1}{N_{w0}} \sum \left\{ \begin{array}{ll} 0 & \text{if prediction is correct} \\ w_i & \text{otherwise} \end{array} \right.$$

#### **Residual Sum of Squares for Classification Trees**

The residual sum of squares (RSS) for classification trees is defined as

$$RSS = \sum_{\lambda} \sum_{\Phi} N_{w\Phi}^{\lambda} \left[ \sum_{\tau \neq \Phi} (P_{w\tau}^{\lambda})^{2} + (1 - P_{w\Phi}^{\lambda})^{2} \right]$$

where

- $\Phi$  is the actual response level
- $N_{\Phi}^{\lambda}$  is the number of observations on leaf  $\lambda$  that have response level  $\Phi$
- $P_{\omega au}^{\lambda}$  is the weighted posterior probability for response level on leaf  $\lambda$ ,

$$P_{w\lambda} = \frac{N_{w\tau}^{\lambda}}{N_{w\lambda}}$$

•  $P_{\omega\Phi}^{\lambda}$  is the weighted posterior probability for the actual response level  $\Phi$  on leaf  $\lambda$ ,

$$P_{w\Phi} = \frac{N_{w\tau}^{\Phi}}{N_{w\lambda}}$$

#### **Average Square Error for Classification Trees**

The average square error (ASE) is also known as the Brier score for classification trees. It is defined as

$$ASE = \frac{RSS}{N_{w0}N_T}$$

where  $N_T$  is the number of levels for the response variable.

#### Sensitivity for Binary Classification Trees

Sensitivity is the probability of predicting an event for the response variable when the actual state is an event. For example, if the event is "an individual is sick," then sensitivity is the probability of predicting that an individual is sick given that the individual is actually sick. For binary classification trees, it is defined as

Sensitivity = 
$$\frac{TP_w}{P_w}$$

where

- TP is the sum of weights of true positives (predicting that an individual is sick)
- P is the sum of weights of positive observations (sick individuals)

#### **Specificity for Binary Classification Trees**

Specificity is the probability of predicting a nonevent for the response variable when the actual state is a nonevent. For example, if the event is "an individual is sick," then specificity is the probability of predicting that an individual is not sick given the fact that the individual is actually not sick. For a binary classification tree, specificity is defined as

Specificity = 
$$\frac{TN_w}{N_w}$$

where

- TN is the sum of weights of true negatives (predicting that an individual is not sick)
- N is the sum of weights of negative observations (healthy individuals)

#### Area under the Curve for Binary Classification Trees

Area under the curve (AUC) is defined as the area under the receiver operating characteristic (ROC) curve. PROC HPSPLIT uses sensitivity as the Y axis and 1 – specificity as the X axis to draw the ROC curve. AUC is calculated by trapezoidal rule integration,

$$AUC = \frac{1}{2} \sum_{\lambda} ((x_{\lambda} - x_{\lambda - 1})(y_{\lambda} + y_{\lambda - 1}))$$

where

- $y_{\lambda}$  is the sensitivity value at leaf  $\lambda$
- $x_{\lambda}$  is the 1 specificity value at leaf  $\lambda$

#### **Confusion Matrix for Classification Trees**

A confusion matrix is also known as a contingency table. It contains information about actual values and predicted values from a classification tree. A confusion matrix has rows and columns, where each row corresponds to the actual response level and each column corresponds to the predicted response level. The

values in the matrix represent the number of observations that have the actual response represented in the row and the predicted response represented in the column. The error rate per actual response level is also reported,

ErrorRate = 
$$\frac{N_{ww}}{N_{w\Phi}}$$

where

- $N_{ww}$  is the sum of weights of wrong predictions
- $N_{w\Phi}$  is the sum of weights of observations that have response level  $\Phi$

#### Measures of Model Fit for Regression Trees

The HPSPLIT procedure measures model fit for regression trees based on RSS and ASE.

#### Residual Sum of Squares for Regression Trees

The residual sum of squares (RSS) for regression trees is defined as

$$RSS = \sum_{\lambda} \sum_{i \in \lambda} w_i \left( y_i - \hat{y}_{\lambda}^T \right)^2$$

where

- i is an observation on leaf  $\lambda$
- $y_i$  is the predicted value of the response variable of observation i
- $\hat{y}_{\lambda}^T$  is the actual value of the response variable on leaf  $\lambda$

#### **Average Square Error for Regression Trees**

The average square error (ASE) for regression trees is defined as

$$ASE = \frac{RSS}{N_{w0}}$$

#### **Random Forest**

#### **SAS - HPFOREST Procedure**

The HPFOREST procedure is a high-performance procedure that creates a predictive model called a forest that consists of several decision trees. A predictive model defines a relationship between input variables and a target variable. The purpose of a predictive model is to predict a target value from inputs. The HPFOREST procedure trains the model; that is it creates the model using training data in which the target values are known. The model can then be applied to observations in which the target is unknown. If the predictions fit the new data well, the model is said to generalize well. Good generalization is the primary goal for predictive tasks. A predictive model might fit the training data well but generalize poorly.

A decision tree is a type of predictive model that has been developed independently in the statistics and artificial intelligence communities. The HPFOREST procedure creates a tree recursively. An input variable

is chosen and used to create a rule to split the data into two segments. The process is then repeated in each segment, and then again in each new segment, and so on until some constraint is met. In the terminology of the tree metaphor, the segments are nodes, the original data set is the root node, and the final unpartitioned segments are leaves or terminal nodes. A node is an internal node if it is not a leaf. The data in a leaf determine the estimates of the value of the target variable. These estimates are subsequently applied to predict the target of a new observation assigned to the leaf.

The HPFOREST procedure creates decision trees that differ from each other in two ways. First, the training data for a tree is a sample, without replacement, from the original training data of the forest. Second, the input variables considered for splitting a node are randomly selected from all available inputs. Among these variables, the HPFOREST procedure considers only a single variable when forming a splitting rule. The chosen variable is the one that is most associated with the target.

PROC HPFOREST runs in either single-machine mode or distributed mode. In distributed mode, PROC HPFOREST trains decision trees in parallel, and accesses all the data for every tree.

#### **Random Forest - Article**

The following material is in a R News article by Andy Liaw and Matthew Wiener<sup>1</sup> A portion of the material has been included here.

Recently there has been a lot of interest in "ensemble learning" – methods that generate many classifiers and aggregate their results. Two well-known methods are boosting (see, e.g., Shapire et al., 1998) and bagging Breiman (1996) of classification trees. In boosting, successive trees give extra weight to points incorrectly predicted by earlier predictors. In the end, a weighted vote is taken for prediction. In bagging, successive trees do not depend on earlier trees – each is independently constructed using a bootstrap sample of the data set. In the end, a simple majority vote is taken for prediction.

Breiman (2001) proposed random forests, which add an additional layer of randomness to bagging. In addition to constructing each tree using a different bootstrap sample of the data, random forests change how the classification or regression trees are constructed. In standard trees, each node is split using the best split among all variables. In a random forest, each node is split using the best among a subset of predictors randomly chosen at that node. This somewhat counterintuitive strategy turns out to perform very well compared to many other classifiers, including discriminant analysis, support vector machines and neural networks, and is robust against overfitting (Breiman, 2001). In addition, it is very user-friendly in the sense that it has only two parameters (the number of variables in the random subset at each node and the number of trees in the forest), and is usually not very sensitive to their values.

The randomForest package provides an R interface to the Fortran programs by Breiman and Cutler (available at http://www.stat.berkeley.edu/users/breiman/). This article provides a brief introduction to the usage and features of the R functions. Suppose that one has a training data set d=(X,y) where X consists of n observations and p dimensions. y is the dependent variable. If y is continuous then the random forest is regression and if y is categorical, the random forest is for classification. Since the random forest is a CART like procedure with bootstrapping, one needs to specify two parameters, the number of bootstrap samples; B = ntree and the number variables used at each split for each of the bootstrap samples,  $m \le p = mtry$ . Note:  $m = \sqrt{p}$  or p/3 are common values for m.

<sup>&</sup>lt;sup>1</sup>included in the course BOX.

#### Algorithm for RF

- 1. Draw *ntree* bootstrap samples from the original data.
- 2. For each of the bootstrap samples, grow an unpruned classification or regression tree, with the following modification: at each node, rather than choosing the best split among all predictors, randomly sample *mtry* of the predictors and choose the best split from among those variables. (Bagging can be thought of as the special case of random forests obtained when *mtry* = p, the number of predictors.)
- 3. Predict new data by aggregating the predictions of the *ntree* trees (i.e., majority votes for classification, average for regression).

An estimate of the error rate can be obtained, based on the training data, by the following:

- 1. At each bootstrap iteration, predict the data not in the bootstrap sample (what Breiman calls "out-of-bag", or OOB, data) using the tree grown with the bootstrap sample.
- 2. Aggregate the OOB predictions. (On the average, each data point would be out-of-bag around 36% of the times, so aggregate these predictions.) Calculate the error rate, and call it the OOB estimate of error rate.

Our experience has been that the OOB estimate of error rate is quite accurate, given that enough trees have been grown (otherwise the OOB estimate can bias upward; see Bylander (2002)).

#### **Bagging the Data**

A decision tree in a forest trains on new training data that are derived from the original training data presented to the HPFOREST procedure. Training different trees with different training data reduces the correlation of the predictions of the trees, which in turn should improve the predictions of the forest.

The HPFOREST procedure samples the original data without replacement to create the training data for an individual tree. Most forest algorithms sample with replacement. The convention of sampling with replacement originated with Leo Breiman's bagging algorithm (Breiman 1996, 2001). The word bagging stems from "bootstrap aggregating," where "bootstrap" refers to a process that uses sampling with replacement. Breiman refers to the observations that are excluded from the sample as out-of-bag (OOB) observations. Therefore, observations in the training sample are called the bagged observations, and the training data for a specific decision tree are called the bagged data. Subsequently, Freedman and Popescu (2003) argued that sampling without replacement can provide more variability between the trees, especially with larger training sets.

The INBAGN= and INBAGFRACTION= options in the PROC HPFOREST statement specify the number of observations to sample without replacement into a bagged data set.

Estimating the goodness-of-fit of the model by using the training data is usually too optimistic; the fit of the model to new data is usually worse than the fit to the training data. Estimating the goodness-of-fit by using the out-of-bag data is usually too pessimistic at first. With enough trees, the out-of-bag estimates are an unbiased estimate of the generalization fit.

#### The R Perspective

There are many slight variations in CART analysis based on almost any data structure permutation we could imagine. If you decide to apply CART in your own work, Google and R web forums will prove to be very

helpful in determining which slight adjustments need to be made now that you are familiar with the basic structure and terminology associated with the procedure. It is appropriate to discuss two commonly used variations: bagging and boosting. Bagging was developed by Breiman and appeared shortly after his seminal work defining the field, and has gained traction following the increased interest in bootstrapping and similar procedures in statistical analysis, and it is useful to think of it as bootstrapping for tree analysis. The name derives from bootstrap aggregating and involves creating multiple similar datasets, re-running the tree analysis, and then collecting the aggregate of the results and re-calculating the tree and associated statistics based on this aggregate. This technique is often used as cross-validation for larger trees a user wishes to prune and where different versions of the same tree have vastly different rates of misclassification. In general, the procedure will improve the results of a highly unstable tree but may decrease the performance of a stable tree. Using the package **ipred** the procedure is easy to implement, and we will briefly present it here using the data from our applied example:

```
mybag =bagging(family medpatient gender+patient age+ patient ethnicity +
patient insurance +...+ comorbidites, data = mydata,nbagg=30,coob=T)
```

where nbagg specifies that the procedure will create 30 full datasets to aggregate and coob specifies the aggregation selection technique, here the averaged model ("out-of-the-bag"). Calling on the command mybag\$err will return the new misclassification error, in our case 23.9% – an unimpressive 0.01 decrease in misclassification. Boosting is a technique that seeks to reduce misclassification by a recursive tree model. Here, classifiers are iteratively created by weighted versions of the sample where the weights are adjusted at each iteration based on which cases were misclassified in the previous step – many "mini-trees" which exhibit continuously decreasing misclassification. This technique is often applied to data which has high misclassification because it is largely uninformative, or a "weak learner." In these data sets classification is only slightly better than a random guess (think misclassification only slightly less than 50%), since the data are so loosely (perhaps because of confounders) related [15]. Implementing boosting is either done through a complex series of packages in R or some third-party software specializing in decision tree analysis. Our results indicate that our data are not weak learners, so we will not implement boosting here; in our case, bagging is much more appropriate. Generally, the data structure will indicate whether boosting or bagging is more appropriate. For more information on boosting in R, consult the **adabag** function.

## Information about the Boston Housing Data

The Boston housing dataset is small, especially in today's age of big data. But there was a time where neatly collected and labeled data was extremely hard to access, so a publicly available dataset like this was very valuable to researchers. And although we now have things like Kaggle and open government initiatives which give us plenty of datasets to choose from, this one is a staple to machine learning practice as chocolate is to a break-up.

Each of the 506 rows in the dataset describes a Boston suburb or town, and it has 14 columns with information such as average number of rooms per dwelling, pupil-teacher ratio, and per capita crime rate. The last row describes the median price of owner-occupied homes (this leaves out homes that are rented out), and it's usually the row that we are trying to predict when we use it for regression tasks. A description of the variables is included in the following figure.

## 7.2.1. Boston house prices dataset

#### **Data Set Characteristics:**

| Number of<br>Instances:                 | 506  |
|---|--|
| Number of<br>Attributes:                | 13 numeric/categorical predictive. Median Value (attribute 14) is usually the target.  |
| Attribute<br>Information<br>(in order): | <ul> <li>CRIM per capita crime rate by town</li> <li>ZN proportion of residential land zoned for lots over 25,000 sq.ft.</li> <li>INDUS proportion of non-retail business acres per town</li> <li>CHAS Charles River dummy variable (= 1 if tract bounds river; 0 otherwise)</li> <li>NOX nitric oxides concentration (parts per 10 million)</li> <li>RM average number of rooms per dwelling</li> <li>AGE proportion of owner-occupied units built prior to 1940</li> <li>DIS weighted distances to five Boston employment centres</li> <li>RAD index of accessibility to radial highways</li> <li>TAX full-value property-tax rate per \$10,000</li> <li>PTRATIO pupil-teacher ratio by town</li> <li>B 1000(Bk - 0.63)^2 where Bk is the proportion of blacks by town</li> <li>LSTAT % lower status of the population</li> <li>MEDV Median value of owner-occupied homes in \$1000's</li> </ul> |
| Missing<br>Attribute<br>Values:         | None   |
| Creator:                                | Harrison, D. and Rubinfeld, D.L.   |

More importantly, Otis W. Gilley also rechecked all of the data against the original census data and found that eight of the median prices in the median value column were plain and simply wrong! This is what he found:

#### Incorrect data

More importantly, Otis W. Gilley also rechecked all of the data against the original census data and found that eight of the median prices in the median value column were plain and simply wrong!

This is what he found:

**Table 1 — Miscoded Dependent Variable Observations** 

| Observation and Tract<br>Number | Median Value | Corrected<br>Median Value | Percentage<br>Error |
|---------------------------------|--------------|---------------------------|---------------------|
| 8-2042                          | 27.1         | 22.1                      | 22.62%              |
| 39-2084                         | 24.7         | 24.2                      | 2.07%               |
| 119-3585                        | 37.0         | 33.0                      | 12.12%              |
| 241-3823                        | 22.0         | 27.0                      | -18.42%             |
| 438-0905                        | 8.7          | 8.2                       | 6.1%                |
| 443-0911                        | 18.4         | 14.8                      | 24.32%              |
| 455-0923                        | 14.9         | 14.4                      | 3.47%               |
| 506-1805                        | 11.9         | 19.0                      | -37.37%             |

Source: Gilley (1996) On the Harrison and Rubinfeld Data

Gilley proceeded to correct the dataset, run the calculations of the original paper on hedonic pricing and check if the results still held true. Luckily for the history of data science, there were no significant changes.

The goodness-of-fit as measured by R2 rises somewhat when employing the corrected observations. However, the magnitudes of the coefficients did not change much and the qualitative results from the original regression still hold.
